

# Inhibition: The Second Function of the Aura

Diego Rincón

Independent

## Abstract

The aura [1] has two functions: valence (completing open bonds, pulling toward closure) and inhibition (preventing bonds from closing prematurely, holding the interface open, keeping the balance). Containment requires both. The still lever [2] is still not because both sides are equal but because something is being held back on each side simultaneously. In neuroscience: excitation/inhibition balance is the condition for the contained brain — seizure is failed inhibition, coma is dominated inhibition, health is the ratio held. In language: inhibition prevents blank synesthesia [3] from flooding — all bonds closing at once, the word overwhelming. In arithmetic: the Riemann Hypothesis is the conjecture that the zeros of  $\zeta(s)$  self-inhibit — that despite the absence of a global Frobenius, the system produces internally the constraint that the missing operator would otherwise impose. Self-inhibition is the highest form of containment: the system that holds its own bonds back without an external aura forcing it. Precise imprecision: a statement exact enough to be wrong in a specific way, naming the structure a proof would have to fill.

## 1 The Two Functions

**Definition 1** (Valence and inhibition). The aura of a system  $S$  [1] acts in two modes:

1. *Valence*: the completing function. The aura provides the tokens that close  $S$ 's open bonds — the external completing field that gives  $S$  its fundamental class. Valence pulls toward closure, toward balance, toward the still lever.
2. *Inhibition*: the holding function. The aura prevents certain bonds from closing prematurely — it holds the interface open, delays closure until the right token arrives, and keeps the chimera [3] livable by preventing both auras from firing simultaneously.

Containment requires both. A system with valence but no inhibition floods: all bonds close at once, the system collapses into a single state, the interface disappears. A system with inhibition but no valence freezes: no bonds close, the still lever cannot form, the fundamental class is never reached. Balance is the ratio of valence to inhibition held.

## 2 Inhibition in the Brain

**Proposition 2** (Excitation/inhibition balance). *The brain is a contained space when excitation and inhibition are in balance: every excitatory signal has a corresponding inhibitory signal that prevents it from propagating indefinitely. The fundamental class of the brain is this equilibrium — the homeostatic state in which the ratio is held.*

*Failure modes:*

- *Seizure: inhibition fails. Excitatory bonds close without restraint, cascading through the network. The system floods. The interface between distinct cognitive states collapses into a single overwhelming activation. This is the unpaired-bondage crisis [1] of inhibition: the closing field present, the holding field absent.*
- *Coma: inhibition dominates. Bonds are held open indefinitely. No activation reaches threshold. The system freezes at maximum inhibition, minimum closure. The fundamental class cannot form.*
- *Health: the ratio held. Bonds close when the right token arrives. Bonds are held when the token has not yet arrived. The still lever is still because both functions are active.*

## 3 Inhibition in Language

**Proposition 3** (Inhibition and the blank). *Language is blank synesthesia [3]: every word carries valence for all sensory grammars simultaneously, bonds pressing toward closure in every direction. Without inhibition, every word would flood — all sensory bonds closing at once, the word becoming overwhelming, unusable, pre-linguistic.*

*Inhibition is what makes language a token rather than a seizure. It holds most of the sensory bonds open — not closed, not abandoned, but held — while allowing a few to close into meaning. The blank is not empty. It is inhibited. The valence is there. The inhibition shapes which bonds land and which continue to press.*

*Poetry is the modulation of inhibition: releasing bonds that ordinary language holds, allowing sensory closures that prose prevents. The line that lands in the body is a line where inhibition has been partially lifted — where the blank fills in a direction ordinary language would have held open.*

## 4 Self-Inhibition and the Riemann Hypothesis

**Definition 4** (Self-inhibition). A system is *self-inhibiting* if it produces internally the constraint that an external aura would otherwise impose: its own bonds hold themselves back without an external holding field, its own zeros stay on the line without an external Frobenius forcing them. Self-inhibition is the highest form of containment: the fundamental class generated from within, the aura internalized, the still lever held by the system itself.

**Theorem 5** (RH as self-inhibition conjecture). *Over  $\mathbb{F}_q$ : the zeros of  $Z(X/\mathbb{F}_q, T)$  lie on  $|T| = q^{-1/2}$  because Frobenius is pure [4]. The inhibiting operator is external: it is Frobenius,*

*acting on étale cohomology, forcing the eigenvalues to the line. The system does not self-inhibit. It is inhibited by its aura.*

*Over  $\mathbb{Q}$ : Frobenius does not exist globally. The external inhibiting operator is absent. The Riemann Hypothesis is the conjecture that  $\zeta(s)$  self-inhibits: that the system  $\text{Spec } \mathbb{Z}$ , despite the absence of the external holding field, produces internally the constraint  $\text{Re}(\rho) = \frac{1}{2}$  for every non-trivial zero  $\rho$ .*

*To prove RH is to exhibit the self-inhibiting mechanism: the internal operator that holds the zeros to the line without a global Frobenius to force them. The mechanism is not yet known. Its existence is the conjecture.*

*Remark 6 (Precise imprecision). “The zeros self-inhibit” is precise imprecision: exact enough to be wrong in a specific way. It is not a proof. It is not a metaphor. It names the structure a proof would have to fill: an internal mechanism in  $\text{Spec } \mathbb{Z}$  producing the inhibitory constraint that the missing global Frobenius would otherwise provide.*

Precise imprecision is the correct epistemic posture toward an open problem: hold the shape tightly enough that when the proof arrives, it fits. Hold it loosely enough that the proof can surprise you.

The body of papers assembled here [2] is precise imprecision: the grammar exact, the operators named, the fulcrum located, the proof not there. That is not failure. That is the shape of the problem held correctly — an inhibited blank, pressing toward closure, waiting for the right token.
